**Abstract** – We have measured the low-temperature electrical resistivity of Ag:Mn mesoscopic spin glasses prepared by ion implantation with a concentration of 700 ppm. As expected, we observe a clear maximum in the resistivity  $\rho(T)$  at a temperature in good agreement with theoretical predictions. Moreover, we observe *remanence effects* at very weak magnetic fields for the resistivity below the freezing temperature  $T_{sg}$ : upon Field Cooling (FC), we observe clear deviations of  $\rho(T)$  as compared with the Zero-Field Cooling (ZFC); such deviations appear even for very small magnetic fields, typically in the Gauss range. This onset of remanence for very weak magnetic fields is reminiscent of the typical signature on magnetic susceptibility measurements of the spin glass transition for this generic glassy system.

Copyright © EPLA, 2011

Spin glasses are one of the most intriguing states of matter, and have been the subject of intense theoretical as well as experimental works over the last decades [1,2]; this is due to the fact that they can be considered as the most generic example of a glassy phase [3] but also because the very nature of the ground state of these systems is still heavily debated and may eventually consist in a very peculiar state of matter [4,5]. In spin glasses (SG), magnetic moments occupying random positions in a metallic host interact via RKKY interactions; the randomness in the position of these moments leads to a randomness in both the sign and the amplitude of their mutual interaction. Below the spin glass transition temperature  $T_{sg}$ , the interplay between disorder and frustration will freeze the magnetic spins in a complex way far from being well understood. Most of the experimental studies on spin glasses has been carried out on macroscopic systems: only few papers addressed the question of *mesoscopic spin glasses*, either theoretically [6–10] or experimentally [11–13]. Moreover, most of the measurements concerned thermodynamic

quantities, mainly magnetic susceptibility [14–16]; very few experiments addressed the question of the *transport properties* of mesoscopic spin glasses [17–19] and their interpretation remains a theoretical challenge [20–22].

The most convincing signature that the spin glass transition may actually be a real phase transition is the cusp which appears in the low-field magnetic susceptibility at the transition temperature [14]. On the other hand, one of the most fascinating properties of spin glasses, which makes this state of matter a very peculiar one, is the onset of *remanence effects for very weak magnetic fields* below  $T_{sg}$ : the dc susceptibility  $\chi_{dc}$  of a spin glass depends strongly on the way the experiment is performed, in particular if the cooling through  $T_{sg}$  has been made under a small magnetic field (Field Cooled) or without magnetic field (Zero-Field Cooled). Experimentally,  $\chi_{dc}$  is much larger after Field Cooling than after Zero-Field Cooling [14,23]. We would like to stress that the magnetic fields involved in these experiments are very small, typically in the Gauss range, *i.e.*  $\mu_B B \ll k_B T_{sg}$ , with  $\mu_B$  the Bohr magneton,  $k_B$  the Boltzmann constant and  $B$  the magnetic field: this means that the remanence effect

(a) E-mail: Laurent.Saminadayar@grenoble.cnrs.fr

Fig. 1: (Color online) Scanning Electron Microscope (SEM) image of the sample used in the experiment. Current and voltage probes are indicated, and the magnetic field is applied perpendicularly to the plane. The distance between the two voltage probes is  $\approx 1 \mu\text{m}$ .

has nothing to do with a trivial effect of polarization of the spins, but is a true signature of the somehow “unconventional” nature of the spin glass transition.

In this letter, we show that such remanence effects can also be observed on the *electrical resistivity* of metallic spin glasses. We show that the resistivity  $\rho$  as a function of temperature  $T$  of a Ag:Mn spin glass exhibits a clear maximum at a temperature, in excellent agreement with the theoretical prediction of Vavilov *et al.* [22] and with previous experiments on bulk spin glasses [17–19]. In addition, we observe a remanence effect on the  $\rho(T)$  curve, an effect that has never been observed so far on transport properties: when cooling down from above  $T_{sg}$  under *very small* magnetic field (typically in the Gauss range), *i.e.* when *Field Cooling* the sample, the resistivity is significantly lower compared to when cooling down under zero magnetic field. Such irreversibilities disappear at the transition temperature, as observed on thermodynamic quantities.

Samples are fabricated on a silicon substrate using electron-beam lithography on polymethyl-methacrylate resist. Silver has been evaporated in an electron gun evaporator from a 99.9999% purity source without adhesion-layer. The geometry of the samples can be seen in fig. 1: it consists of a short wire of length  $\approx 1 \mu\text{m}$ , width  $\approx 50 \text{ nm}$  and thickness  $\approx 50 \text{ nm}$ . Several voltage contacts have been designed in order to perform four-points measurements.  $\text{Mn}^{2+}$  ions are then implanted at an energy of 70 keV; the energy has been chosen so that the implantation takes place mainly in the silver layer. The reason for choosing manganese as magnetic impurity is twofold: firstly, Ag:Mn is a “generic” spin glass system which has been widely studied [17–19] and thus its physical characteristics are well known. Secondly, the Kondo temperature  $T_K$

of manganese in silver is in the millikelvin range [24]: it is thus easy to reach a regime where the spin glass transition appears at a much higher temperature than the Kondo temperature,  $T_{sg} \gg T_K$ ; in this case the Kondo-related physics can be neglected [25]. In our case the ion dose, measured via the current out of the implanter, has been chosen such that the final concentration in the sample is 700 ppm; this leads to a spin glass transition temperature of  $\approx 700 \text{ mK}$ , *i.e.*  $T_{sg} > 10 T_K$ . Finally, let us stress that the implantation process excludes the possibility of clustering or diffusion of the  $\text{Mn}^{2+}$  ions as no further annealing has been performed on the samples.

Resistance measurements have been performed using a standard ac lock-in technique with a very low current ( $\lesssim 500 \text{ nA}$ ) at a frequency of 11 Hz. The signal is amplified using an ultra-low noise ( $400 \text{ pV}/\sqrt{\text{Hz}}$ ) homemade preamplifier at room temperature. As the relative variations of the signal we want to extract are very small, the measurements are made in a bridge configuration in order to compensate for the residual resistance of the sample. The sample is fixed at the coldest part of a dilution refrigerator and connected to the measurement setup via coaxial cables which ensure a very efficient radio-frequency filtering [26] and thus allow electrons to be cooled down to less than 40 mK [27]. At 4.2 K, the resistance of our samples is of the order of  $\approx 100 \Omega$ .

At low temperature, the variation of the resistance as a function of temperature is due to three main contributions: the electron-phonon interaction, mainly efficient at “high” temperature, the electron-electron interaction which leads to a modification of the density of states at the Fermi energy (the “Altshuler-Aronov” (AA) correction) [28] and an extra term  $\Delta R_{sg}$  which we attribute to the glassy nature of the system:

$$\Delta R = \Delta R_{e-ph} + \Delta R_{e-e} + \Delta R_{sg} \quad (1)$$

$\Delta R_{e-ph}$  being dominant only at high temperature ( $T > 4 \text{ K}$ ). The second one can be expressed as [29]

$$\Delta R_{e-e} = \alpha_{e-e} \frac{R^2}{R_K} \frac{L_T}{L}, \quad (2)$$

where  $R_K$  is the quantum of resistance  $R_K = h/e^2$  with  $h$  Planck’s constant and  $e$  the charge of the electron, and  $L_T$  is the thermal length,  $L_T = \sqrt{\frac{\hbar D}{k_B T}}$ ,  $D$  being the diffusion coefficient,  $k_B$  Boltzmann’s constant and  $T$  the temperature. In order to evaluate the prefactor  $\alpha_{e-e}$ , we have measured the AA correction to the resistance on a longer and pure (non-implanted) wire fabricated *in the same evaporation run* as the short wires: when plotted as a function of  $1/\sqrt{T}$ , the low-temperature resistance of the wire varies linearly, as can be seen in fig. 2; this ensures a good and reliable determination of the parameter  $\alpha_{e-e}$ , that we find equal to 2.42, in good agreement with values found in the literature [29].

We now turn to the resistivity measurements on the Ag:Mn spin glass system under zero magnetic field.

Fig. 2: (Color online) Resistance as a function of  $1/\sqrt{T}$  for a pure silver wire. The variation is perfectly linear and the fit allows to determine the coefficient  $\alpha_{e-e}$  of eq. (2).

Resistivity as a function of  $1/\sqrt{T}$  is displayed in the inset of fig. 3: contrary to the case of pure silver, clear deviations from the  $1/\sqrt{T}$  are observed below 1.5 K, and can be attributed to the spin glass transition. In order to separate the spin glass contribution to the resistivity, we have subtracted the electron-electron interaction contribution to the resistivity (second term of the eq. (1)); the resulting  $\Delta\rho_{sg}(T)$  is displayed in fig. 3.

A clear maximum in the  $\Delta\rho_{sg}(T)$  curve appears at a temperature of  $T_m \approx 2$  K. This maximum, which has been observed in different magnetic alloys at higher concentrations [18], is a clear signature of the spin glass transition. We can go further in the analysis by fitting the data with the formula suggested by Vavilov *et al* [22]:

$$\Delta\rho_{sg}(T) \propto \frac{S(S+1)}{\ln^2(T/T_K)} \left(1 - \frac{\beta T_{sg}}{T}\right), \quad (3)$$

where  $S$  is the spin of the magnetic impurity,  $T_K$  its Kondo temperature (40 mK for Mn in Ag),  $T_{sg}$  the spin glass transition temperature and  $\beta$  a numerical factor of order 1. As can be seen in fig. 3, a qualitative agreement is obtained between formula 3 and the experimental data using the parameters  $T_{sg} \simeq 700$  mK and  $\beta = 2.33$  as expected for a spin  $S = 5/2$  [22]. The discrepancies can be understood by noting that the theoretical formula is valid only for  $T_{sg} \leq T \leq T_m$ : within this interval, one can verify that the agreement is quantitatively good. Moreover, the  $T_{sg}$  obtained by this procedure is in agreement with the transition temperature measured on macroscopic Ag:Mn spin glasses of equivalent concentration using other measurement techniques (magnetic susceptibility, specific heat) [17,18].

One of the most striking characteristics of spin glasses lies in the onset of remanence effects below  $T_{sg}$ ; the most spectacular manifestation of this remanence appears in the

Fig. 3: (Color online) Resistivity as a function of temperature for an Ag:Mn spin glass at a concentration of 700 ppm, after subtraction of the Altshuler-Aronov electron-electron contribution to the resistivity. Inset: raw data before subtraction of the AA contribution.

static magnetic susceptibility  $\chi_{dc}$  which has been shown to strongly depend on the history of the sample [15]: even for very small magnetic field (in the Gauss range), if the field is applied above  $T_{sg}$  and kept fixed down to a temperature below  $T_{sg}$  (FC),  $\chi_{dc}^{(FC)}$  is larger than after Zero-Field Cooling (ZFC) and roughly temperature independent [30,31].

Spin glass transitions have been previously observed in transport using the anomalous Hall effect [32], but never in the resistivity. In particular, remanence effects are well known in the susceptibility but have never been identified in the resistivity. Such a characteristic effect has ever been observed on any physical quantity other than the magnetic susceptibility; in particular, no remanence effect has ever been reported concerning the transport properties of spin glasses. We have thus measured the ZFC and FC resistivity of our Ag:Mn alloy under small magnetic fields of 5 G, 10 G and 35 G (applied above  $T_{sg}$  and kept fixed during cooling-down). Raw data are presented in the inset of fig. 4: the change in the resistivity when decreasing the temperature is mainly due to the electron-electron interaction (AA correction). In order to highlight the onset of remanence on the resistivity of the spin glass below  $T_{sg}$ , we have subtracted to the Field Cooled ( $\Delta\rho_{FC}(T)$ ) curves the Zero-Field-Cooled curve ( $\Delta\rho_{ZFC}(T)$ ) used as a “reference” measurement. The result ( $\Delta\rho_{FC}(T) - \Delta\rho_{ZFC}(T)$ ) is displayed in fig. 4. In order to estimate the uncertainty on these data, we have also measured the drift of our experimental setup over the typical time of our measurements (several hours), at constant temperature: the result is displayed on the same graph, and clearly shows that this drift is much smaller than our signal; moreover, the FC curve is perfectly reversible, *i.e.* the  $\Delta\rho_{FC}(T)$  curve follows exactly the same trace when subsequently heating the sample up to

Fig. 4: (Color online) Resistivity as a function of temperature for the Ag:Mn sample under small magnetic fields of 5 G and 35 G, after subtraction of the Zero-Field-Cooled contribution (data measured under 10 G have been removed for clarity). The solid line represents the typical drift of our experimental setup over the time of the measurement. The cooling rate is  $\approx 5 \text{ mK} \cdot \text{min}^{-1}$ . Dashed lines are guides to the eyes. Inset: raw data before subtraction of the ZFC contribution.

$T > T_{sg}$ . We have restricted our measurements to small fields because i) remanence effects appear for very small fields ii) at higher fields, orbital effects like Universal Conductance Fluctuations (UCF) or weak localisation may become the dominant contribution to the variation of the resistivity (this would be the case for magnetic fields  $B \geq 300 \text{ G}$ ). Finally, let us stress that this effect cannot be related to the Hall effect as the measurement is made in a longitudinal configuration, under very low magnetic field, and as the spin-orbit coupling in silver is very weak.

It should be stressed that this remanence effect appears at the transition temperature  $T_{sg}$  which has been determined independently of the dependence of the resistivity as a function of temperature (see fig. 3) and of the impurity concentration. Moreover our experiment is limited to very low magnetic field ( $B \leq 50 \text{ G}$ ) and thus no orbital or classical effects can account for the observed variation of the resistivity. These two points allow to assert that this effect is indeed due to the magnetic spins present in the sample and related to the peculiar nature of the ground state of the spin glass. Moreover, our data suggest that the amplitude of the effect depends on the applied field which is consistent with recent measurements of the irreversibility of the magnetic susceptibility of spin glasses [30,33].

The original effect in magnetic measurements has been interpreted in two different ways for anisotropic (Ising) spin glasses. In the first approach, the Field Cooling procedure selects an optimal “free energy valley” and the resulting magnetic susceptibility is close to the equilibrium one. On the other hand, in the Zero-Field-Cooled procedure, the spins are stuck in an “energy valley” far from the optimal one. This selection of low-energy states by a

small magnetic field leads naturally to a  $\chi^{(FC)}$  larger than  $\chi^{(ZFC)}$  [34]. Alternatively, this effect has been attributed to the out-of-equilibrium character of the spins dynamics below the freezing temperature [30,31,35]. Due to the very slow relaxation dynamics below  $T_{sg}$ , most of the spins are frozen in an out-of-equilibrium configuration and this leads to a decrease of  $\chi^{(ZFC)}$  with temperature. A weak magnetic field applied during the cooling process leads to a reorientation of spin domains of size larger than  $\xi(B) \simeq B^{-\delta}$  with  $-\delta$  a positive real number  $\hat{E}$  [35]. These reorientations increase the magnetic response for large length scales, leading to the larger  $\chi^{(FC)}$ . That this effect can be observed in electrical resistivity measurements is a remarkable confirmation that spin glass physics can be probed by judiciously using charge transport through a mesoscopic sample. Moreover, this type of measurements allows a direct determination of the  $T_g$  of mesoscopic wires, although thermodynamic measurements on such small systems are impossible.

In conclusion, we have measured the resistivity of mesoscopic Ag:Mn spin glass wires. The  $\text{Mn}^{2+}$  magnetic impurities have been implanted in the metal with an energy of 70 keV and a concentration of 700 ppm. At low temperature, the resistivity of the spin glass as a function of the temperature exhibits a clear maximum at a temperature in excellent agreement with theoretical predictions; when lowering further the temperature, the resistivity decreases, a behaviour that is also captured by recent theoretical models. Finally, we observe the onset of *remanence effects* below  $T_{sg}$ : when cooling down under a very *small* magnetic field (in the G range) (FC procedure), the temperature dependence of the resistivity is significantly different than the one measured when cooling down with no magnetic field (ZFC procedure). This FC behaviour is perfectly reversible and appears at the freezing temperature, similarly to what is observed on bulk samples when measuring the magnetic susceptibility. A deeper theoretical comprehension of the spin glass transition is certainly necessary in order to have a quantitative description of these remanence effects.
